(Dated: July 28, 2010)

We use new kinematic data from the ultra-faint Milky Way satellite Segue 1 to model its dark matter distribution and derive upper limits on the dark matter annihilation cross-section. Using gamma-ray flux upper limits from the Fermi satellite and MAGIC, we determine cross-section exclusion regions for dark matter annihilation into a variety of different particles including charged leptons. We show that these exclusion regions are beginning to probe the regions of interest for a dark matter interpretation of the electron and positron fluxes from PAMELA, Fermi, and HESS, and that future observations of Segue 1 have strong prospects for testing such an interpretation. We additionally discuss prospects for detecting annihilation with neutrinos using the IceCube detector, finding that in an optimistic scenario a few neutrino events may be detected. Finally we use the kinematic data to model the Segue 1 dark matter velocity dispersion and constrain Sommerfeld enhanced models.

I. INTRODUCTION

The Fermi Gamma-ray Space Telescope and the current generation of Imaging Atmospheric Cherenkov Telescopes (ACTs) such as VERITAS, MAGIC, HESS, and CANGAROO, are exploring the gamma-ray sky to unprecedented accuracy. Additionally, neutrino detectors such as IceCube will be probing the neutrino sky with greater sensitivity, lower energy thresholds, and finer angular resolution than achieved to date. If weakly interacting massive particles (WIMPs) constitute the dominant component of the dark matter in the Universe, experiments such as Fermi, ACTs, and IceCube may be sensitive to their annihilation or decay products.

Dark matter dominated Milky Way (MW) satellite galaxies are excellent targets to search for dark matter annihilation products, because they are nearby and largely free of astrophysically-produced high energy photons. Among the population of MW satellites, of particular interest is the ultra-low luminosity object Segue 1, which was discovered in 2006 as an overdensity of resolved stars in the Sloan Digital Sky Survey (SDSS) [1] at a heliocentric distance of 23 ± 2 kpc. Originally classified as a tidally-disrupted globular cluster, follow-up spectroscopy for individual stars has revealed that Segue 1 is the least luminous and most dark-matter dominated galaxy known [2]. Though its proximity to the Sagittarius stream has led to a suggestion that Segue 1 is a dissolved star cluster originally associated with the Sagittarius dwarf galaxy [3], new measurements of Segue 1 member stars strongly support that it is indeed a dark matter dominated object [4, 5].

Given its location at 23 ± 2 kpc and the fact that it is dark matter dominated, Segue 1 is an ideal source for dark matter studies [2, 4]. Since Segue 1 can be eas-

ily localized, any signal or limit on high energy gamma-ray/neutrino emission from it is more straightforward to interpret than a corresponding diffuse signal from the Milky Way halo. As we show in this paper, the integral over the square of the dark matter density distribution is similar to, and potentially larger than, the same quantity for all other known Milky Way satellites.

In this work we give the cross-section exclusion regions for dark matter annihilation into a variety of Standard Model particles using gamma-ray flux upper limits for Segue 1. We also give exclusion regions for dark matter annihilation to charged leptons, where an accompanying gamma-ray signal is guaranteed to exist from “final-state radiation” (FSR) [6–8]. The resulting flux from FSR photons is independent of the astrophysical environment in which the photons are produced (as opposed to inverse Compton or synchrotron processes). Neutrino production is also guaranteed from the decay of muon or tau leptons, and we also investigate the case in which dark matter annihilates purely into neutrinos.

Constraints on dark matter annihilation to charged leptons are particularly relevant in light of the positron results from the PAMELA satellite in the energy range of 10-100 GeV [9] as well as the Fermi [10] and HESS [11, 12] $e^+ + e^-$ spectra at $\sim 0.3 - 1$ TeV. If dark matter annihilation is responsible for these measurements, the annihilation cross-section must be $\mathcal{O}(100 - 1000)$ times larger than the thermal freeze-out cross-section and only a small number of anti-protons can be created in the annihilation process [13–20]. Given the importance of the dark matter interpretation of these measurements, and the fact that more precise e^+/e^- flux measurements may not conclusively determine their origin (given the uncertainty in the e^+/e^- propagation in the Galaxy and in their background fluxes), independent checks of the dark

matter interpretation of the PAMELA, Fermi, and HESS signals are of the utmost importance.

Here we present annihilation cross-section constraints from the 9-month Fermi gamma-ray flux upper limits for Segue 1. We also present constraints from gamma-ray flux upper limits obtained by MAGIC. If dark matter annihilation is responsible for the electron and/or positron signals observed by PAMELA and/or Fermi/HESS, we also show that the ACTs MAGIC and VERITAS have excellent prospects for testing models and detecting dark matter by observations of Segue 1. Finally, we investigate the prospects for detecting a neutrino signal from dark matter annihilation in Segue 1 with IceCube, and we give constraints on Sommerfeld enhanced models. Regarding Sommerfeld models that explain both Fermi and PAMELA, we find that current limits slightly disfavor light mediators of mass $\mathcal{O}(0.1 \text{ GeV})$ if we take the mean value for the Segue 1 line-of-sight integral of the dark matter halo density-squared.

II. FLUX CALCULATION

The gamma-ray/neutrino flux from annihilating dark matter is

$$\frac{dN_i}{dAdt} = \frac{1}{8\pi} \mathcal{L}_{\text{ann}}(\rho^2(r), D) \frac{\langle \sigma v \rangle}{m_\chi^2} \int_{E_{th}}^{E_{max}} \frac{dN_i}{dE_i} dE_i \quad (1)$$

where m_χ is the dark matter particle mass, $\langle \sigma v \rangle$ is the annihilation cross-section, E_{th} is the threshold energy of a given gamma-ray/neutrino instrument, and E_{max} is the maximum energy of the photons/neutrinos. The integral over $\frac{dN_i}{dE_i}$ depends only on the particle physics details of the dark matter annihilation. $\mathcal{L}_{\text{ann}}$ is the line-of-sight integral over the square of the dark matter density

$$\mathcal{L}_{\text{ann}} = \int_0^{\Delta\Omega} \left\{ \int_{LOS} \rho^2(r) ds \right\} d\Omega \quad (2)$$

and depends only on the properties of the dark matter halo and the solid angle over which it is observed. Here $\rho(r)$ is the halo dark matter density profile, $r = \sqrt{D^2 + s^2 - 2sD\cos\theta}$ for a halo at a distance D , and the integral is performed along the line of sight over a solid angle $\Delta\Omega = 2\pi(1 - \cos\theta)$. Here we assume $\langle \sigma v \rangle$ is constant throughout the halo.

Dark Matter Distribution — To determine $\mathcal{L}_{\text{ann}}$ we use the new sample of line-of-sight velocities of Segue 1 member stars from [4, 5]. This sample consists of 71 probable member stars (as compared to the sample of 24 members used in previous indirect detection studies [2, 21–24]). In our calculations we include 66 stars, excluding from the sample of 71 two RR Lyrae variable stars and two probable binaries identified in [4], and also excluding the star SDSSJ100704.35+160459.4 which is a 6σ outlier from the mean velocity of Segue 1 [98]. (See [4] for a detailed discussion of these stars and the sample in general, including the effects of binary star contamination

Within a radius of θ (degree)	$\mathcal{L}_{\text{ann}}$ $\log_{10}[\mathcal{L}_{\text{ann}}/(\text{GeV}^2\text{cm}^{-5})]$
0.01	18.3 ± 0.9
0.1	19.0 ± 0.6

TABLE I: Segue 1 $\mathcal{L}_{\text{ann}}$ values within different angular regions, with $\theta = 0.25^\circ$ corresponding to the radius of the outermost confirmed member star.

[25].) We adopt the maximum likelihood procedure that is described in detail in [21, 26], and review the aspects of the calculation that are important for the purposes of this paper. We assume a gaussian likelihood in the distribution of stellar velocities, with a dispersion given by the quadrature sum of the measurement uncertainty of each stellar velocity and the intrinsic dispersion, the latter of which is given by a solution to the Jeans equation. The Jeans equation takes as input the dark matter density profile, stellar density profile, and the stellar velocity anisotropy. We assume that the dark matter and stellar density profiles are independent. For the dark matter density profile we assume a three-parameter Einasto profile, $\rho(r) = \rho_s \exp\left\{-\frac{2}{\alpha}\left[\left(\frac{r}{r_s}\right)^\alpha - 1\right]\right\}$. A profile of this form is motivated by numerical simulations, which suggest that $\alpha = 0.17$ provides a good fit for dark matter halos over a wide variety of mass scales [27]. (Though we use the Einasto parameterization in this paper, the results we present would not change if we use a different parameterization, e.g. the generalized NFW model considered in [22].) For simplicity in this paper we consider isotropic models with $\beta = 0$; we find that this restriction has minimal impact on our resulting constraints. The Segue 1 three-dimensional stellar density profile used in the Jeans equation is taken as a Plummer profile, $\rho(r) \propto (1 + r^2/r_p^2)^{-5/2}$, where $r_p = 30 \text{ pc}$. We take uniform priors on the following parameters over the following ranges: $\alpha \in [0.14 : 0.3]$, $r_s/\text{kpc} \in [0.01 : 0.6]$, and $\log_{10}[\rho_s/(\text{M}_\odot\text{kpc}^{-3})] \in [6 : 10]$. We then marginalize over the gaussian likelihood to construct the likelihood for these parameters. Note that given our assumption of uniform priors the likelihood is equivalent to the posterior probability density distribution for the parameters.

From the likelihood for the parameters ρ_s , r_s , and α , we construct the likelihood for $\mathcal{L}_{\text{ann}}$ using Eq. (2). To remain conservative we integrate the density squared within a solid angle of $\theta = 0.25^\circ$, corresponding to 100 pc. This is close to the radius of the outermost known bound star in the Segue 1 population, which lies at 87 pc. We fit gaussians to the log of the $\mathcal{L}_{\text{ann}}$ likelihood, and for Segue 1 we find

$$\mathcal{L}_{\text{ann}}^{\text{Segue1}} = 10^{19.1 \pm 0.6} \text{ GeV}^2 \text{ cm}^{-5}, \quad (3)$$

with 1σ error bars and θ within 0.25° . See Table I for

$\mathcal{L}_{\text{ann}}$ values of Segue 1 within other radii.

For the calculations below of the expected Sommerfeld enhancement, we are also interested in the velocity dispersion of the dark matter. Segue 1 is a particularly interesting, if not the most interesting, galaxy to consider in the context of Sommerfeld enhanced models because of its extremely low velocity dispersion. In our calculations we will consider the one-dimensional radial dark matter velocity dispersion, σ_r , averaged over the three-dimensional dark matter mass distribution. We define this quantity as

$$\langle \sigma_r^2 \rangle = \frac{\int \rho(r) \sigma_r^2 r^2 dr}{\int \rho(r) r^2 dr}, \quad (4)$$

where $\rho(r)$ is the Einasto profile as above. From a given density profile, the one-dimensional dispersion σ_r^2 is derived from the Jeans equation, assuming that the dark matter velocity dispersion is isotropic. The likelihood for this quantity may then be determined from our base set of three parameters in a manner similar to the derivation of $\mathcal{L}_{\text{ann}}$. We find

$$\sqrt{\langle \sigma_r^2 \rangle} \simeq 4.5 \pm 1.8 \text{ km/s}. \quad (5)$$

We stress again that this quantity is the radial velocity dispersion of the dark matter, which we find to have a mean that is slightly larger than the observed line-of-sight velocity of stars reported in Ref. [4].

The value of $\mathcal{L}_{\text{ann}}^{\text{Segue1}}$ can be compared with a canonical value from the Galactic center. Using an Einasto density profile with standard Milky Way fit parameters, $\rho_s = 0.06 \text{ GeV/cm}^3$ and $r_s = 20 \text{ kpc}$ [28], we find $\mathcal{L}_{\text{ann}}^{\text{MW}} = 10^{20.82} \text{ GeV}^2 \text{ cm}^{-5}$ within a radius of 0.25° . Although this is about two orders of magnitude larger than the mean value of $\mathcal{L}_{\text{ann}}^{\text{Segue1}}$ within the same solid angle, the large astrophysical background in the Galactic center makes Segue 1 a much cleaner target. Moreover, the Milky Way density profile is estimated from simulations that have not included the effect of baryons, whose impact on the density profile is not clear. In addition, these simulations assume that the dark matter is cold (e.g. a thermal WIMP or an axion), but a non-thermal WIMP, or a WIMP with non-negligible self-interactions, could give different halo profiles [29]. Though the Milky Way dark matter distribution can be probed by stellar kinematics on larger scales (e.g. [30]), the distribution near the Galactic Center (within less than ~ 100 s of pc), where most of the annihilation flux emanates, is currently completely unknown.

The mean value of $\mathcal{L}_{\text{ann}}$ for Segue 1 is the same as for Draco [31], and is larger than that for any other known dwarf. Although previous studies have derived larger $\mathcal{L}_{\text{ann}}$ values for Willman 1 and Sagittarius [22], neither system appears to be in dynamical equilibrium [32, 33], which makes constraints on their dark matter halos from existing data unreliable.

Gamma-rays from Dark Matter — For the direct annihilation channels into leptons, $\chi\chi \rightarrow \ell\bar{\ell}$, where ℓ is

a lepton, the energy spectrum from final state radiation (FSR) is given by

$$\frac{dN_\gamma}{dy} = \frac{\alpha}{\pi} \left(\frac{1 + (1-y)^2}{y} \right) \left(\ln \left(\frac{s(1-y)}{m_\ell^2} \right) - 1 \right) \quad (6)$$

[7, 8, 18, 34–36]. Here $\alpha \simeq 1/137$, $y = E_\gamma/m_\chi$, $s = 4m_\chi^2$, and $E_{\text{max}} = m_\chi$ in Eq. (1). This formula holds in the collinear limit, where the photon is emitted collinearly with one of the leptons and $m_\ell \ll m_\chi$.

For the channels that include τ 's, the photon contribution from τ decays into π^0 's (which then decay to γ 's) dominates over the FSR signal, and the energy spectrum is given in [22, 37]. The energy spectrum for FSR for the channel $\chi\chi \rightarrow \phi\phi \rightarrow \ell\bar{\ell}\ell\bar{\ell}$ is given explicitly in [22]. If the final state includes μ 's, we also include photons from the radiative decay of the muon, e.g. $\mu^- \rightarrow e^- \nu_\mu \bar{\nu}_e \gamma$, using the formulas found in e.g. [22, 38, 39]. We do not consider gamma-ray signals from synchrotron radiation or inverse Compton scattering as both are expected to be negligible in Segue 1.

For dark matter annihilation into W^+W^- (W bosons), $b\bar{b}$ (bottom quarks), $t\bar{t}$ (top quarks), and $g\bar{g}$ (gluons), we use the photon spectra from DarkSUSY [41, 42]. Photons produced from these annihilation channels tend to be softer than FSR photons, but more numerous. This makes Fermi more sensitive than ACTs to these annihilation channels. For example, for the Wino LSP model [40] that explains the PAMELA e^+ and $\bar{p}$ data (but not the Fermi or HESS $e^+ + e^-$ data), the dominant channel is $\chi\chi \rightarrow W^+W^-$, and the photon contribution comes from W decays generating π^0 's and hence γ 's. To compare with Fermi flux upper limits, the relevant integral over dN_γ/dE_γ for this model is given by $\int_{100 \text{ MeV}}^{m_\chi} (dN_\gamma/dE_\gamma) dE_\gamma \simeq 27.14$, where $m_\chi \simeq 180 \text{ GeV}$ [40]. Since most of the photons have energies around 1 GeV, ACTs will not be very constraining for this model even if they lower their energy threshold to $\sim 50 \text{ GeV}$.

Neutrinos from Dark Matter — We estimate the number of muons detected by IceCube from muon neutrinos coming from dark matter annihilation in Segue 1 following e.g. [39, 43] (see also [44]). We consider the direct channel $\chi\chi \rightarrow \nu_\mu \bar{\nu}_\mu$, which gives a good indication of how well IceCube could do in a “best-case” scenario, as well as the two channels $\chi\chi \rightarrow \mu^+ \mu^-$ and $\chi\chi \rightarrow \phi\phi$ with $\phi \rightarrow \mu^+ \mu^-$ (we do not consider channels with taus, although their decay would also produce neutrinos). The muon decays $\mu^- \rightarrow \gamma \nu_\mu \bar{\nu}_e e^-$ and $\mu^+ \rightarrow \gamma \bar{\nu}_\mu \nu_e e^+$ produce both electron and muon (anti-)neutrinos. The neutrino energy spectra for the direct channel $\chi\chi \rightarrow \nu_\mu \bar{\nu}_\mu$ is given by

$$\frac{dN_\nu}{dE_\nu} = 2\delta(E_\nu - m_\chi), \quad (7)$$

while for the channel $\chi\chi \rightarrow \mu^+ \mu^-$ we have

$$\frac{dN_{\nu_e}}{dx} = 2 - 6x^2 + 4x^3 \quad (8)$$

$$\frac{dN_{\nu_\mu}}{dx} = \frac{5}{3} - 3x^2 + \frac{4}{3}x^3. \quad (9)$$

FIG. 1: Current exclusion regions from Fermi 9-month gamma-ray observations of Segue 1 (bounded below by the blue solid diagonal line) and MAGIC gamma-ray observations of Segue 1 (bounded below by the purple solid curved line). The exclusion regions use the conservative 2σ lower limit of $\mathcal{L}_{\text{ann}}$ given in Table I within $\theta = 0.25$ (Fermi) and $\theta = 0.1$ (MAGIC). The dashed blue and purple lines depict the respective cross-section bounds using the optimistic 2σ upper limits of $\mathcal{L}_{\text{ann}}$. For the $\chi\chi \rightarrow W^+W^-$ channel, the black dot is the region favored by a model of wino-like neutralinos that explains the PAMELA positron data [40]. Note that $m_\chi \gtrsim m_t \simeq 175$ GeV for the $\chi\chi \rightarrow t\bar{t}$ channel.

The energy spectra for the longer channel $\chi\chi \rightarrow \phi\phi$ with $\phi \rightarrow \mu^+\mu^-$ are given by

$$\frac{dN_{\nu_e}}{dx} = -\frac{5}{3} + 3x^2 - \frac{4}{3}x^3 + 2 \ln \frac{1}{x} \quad (10)$$

$$\frac{dN_{\nu_\mu}}{dx} = -\frac{19}{18} + \frac{3}{2}x^2 - \frac{4}{9}x^3 + \frac{5}{3} \ln \frac{1}{x}, \quad (11)$$

where $x = E_\nu/m_\chi$ [39]. (The ν_i and $\bar{\nu}_i$ spectra are the same for each channel). When these neutrinos reach Earth, the probability that ν_i will have oscillated into ν_μ is roughly [45]

$$\begin{aligned} P(\nu_\mu \rightarrow \nu_\mu) &\simeq P(\bar{\nu}_\mu \rightarrow \bar{\nu}_\mu) \simeq 0.39, \\ P(\nu_e \rightarrow \nu_\mu) &\simeq P(\bar{\nu}_e \rightarrow \bar{\nu}_\mu) \simeq 0.22 \end{aligned} \quad (12)$$

(we take this oscillation probability also into account for the direct channel $\chi\chi \rightarrow \nu_\mu\bar{\nu}_\mu$). Since Segue 1 lies in the

Northern Hemisphere, these neutrinos travel through the Earth towards IceCube. While ν_e and ν_τ predominantly give rise to cascade-like events in IceCube, ν_μ 's can convert to muons in the ice and produce track-like events that yield much better angular resolution [46]. We thus focus exclusively on detecting the muons from the ν_μ 's. (In particular, we also ignore the muons produced from $\nu_\tau \rightarrow \tau \rightarrow \mu$.)

Given $dN_{\nu_\mu, \bar{\nu}_\mu}/dE_\nu$ above, one obtains the differential neutrino flux, $d\Phi_{\nu_\mu, \bar{\nu}_\mu}/dE_\nu$, from Eq. (1). The muon energy spectrum detected by IceCube in a time T is given by

$$\begin{aligned} \frac{N_\mu}{dE_\mu}(E_\mu) &= T \int_{E_\mu}^{m_\chi} dE_\nu \frac{\rho_m}{m_N} \frac{d\Phi_{\nu_\mu, \bar{\nu}_\mu}}{dE_\nu} \left(\frac{d\sigma_\nu}{dE_\mu} + \frac{d\sigma_{\bar{\nu}}}{dE_\mu} \right) \\ &\quad \times R(E_\mu, E_{\text{th}}) A_{\text{eff}}(E_\mu). \end{aligned} \quad (13)$$

FIG. 2: Current exclusion regions from Fermi 9-month gamma-ray observations of Segue 1 (bounded below by the blue solid diagonal line) and MAGIC gamma-ray observations of Segue 1 (bounded below by the purple solid curved line). The exclusion regions use the conservative 2σ lower limit of $\mathcal{L}_{\text{ann}}$ given in Table I within $\theta = 0.25$ (Fermi) and $\theta = 0.1$ (MAGIC). The dashed blue and purple lines depict the respective cross-section bounds using the optimistic 2σ upper limits of $\mathcal{L}_{\text{ann}}$. Green and orange regions indicate the best-fit regions to explain the PAMELA and Fermi e^+/e^- signals and are adapted from [20] after rescaling from a local dark matter density of $0.3 \text{ GeV}/\text{cm}^3$ to $0.43 \text{ GeV}/\text{cm}^3$ [47].

Here the differential cross-section for a neutrino of energy

E_ν to scatter off a nucleon with mass m_N is roughly given

FIG. 3: **Left:** Projected number of muon signal events coming from neutrinos originating from dark matter annihilation directly into $\nu_\mu\bar{\nu}_\mu$ in Segue 1, after 10 years of observation with IceCube, and assuming the mean value of $\mathcal{L}_{\text{ann}}^{\text{Segue1}}$ given in Eq. (3). **Right:** Prospective exclusion regions for IceCube 10-year observations of Segue 1, assuming (signal muon events)/ $\sqrt{\text{signal} + \text{background}}$ muon events ≥ 2 . The muons observed by IceCube are assumed to come from muon neutrinos produced in dark matter annihilation. Here the solid (dashed) line uses the 2σ lower (upper) limit on $\mathcal{L}_{\text{ann}}$ in Eq. (3).

by [48, 49]

$$\frac{d\sigma_\nu}{dE_\mu} \simeq \frac{2m_N G_F^2}{\pi} \left(0.20 + 0.05 \frac{E_\mu^2}{E_\nu^2} \right) \quad (14)$$

while for an anti-neutrino the numbers 0.20 and 0.05 are interchanged. For this expression, we took the average of the scattering cross-sections off a neutron and off a proton, and we assumed $E_\nu \ll m_W^2/m_N \sim 7$ TeV, where m_W is the W boson mass. (For dark matter masses of ~ 10 TeV that give rise to neutrinos of ~ 10 TeV, the constraints we obtain will thus be optimistic by a factor of a few.) Once produced at an energy E_μ , a muon will lose energy according to

$$\frac{dE_\mu}{dr} \simeq -\rho_m(\alpha + \beta E_\mu), \quad (15)$$

where $\alpha \simeq 2 \times 10^{-3} \text{ GeV cm}^2 \text{ g}^{-1}$, $\beta \simeq 4.2 \times 10^{-6} \text{ cm}^2 \text{ g}^{-1}$ [45], and ρ_m is the Earth matter density. If we require that the muon be detected above an energy threshold of E_{th} , it will travel a distance

$$R(E_\mu, E_{\text{th}}) \simeq \frac{1}{\rho_m \beta} \ln \left(\frac{\alpha + \beta E_\mu}{\alpha + \beta E_{\text{th}}} \right). \quad (16)$$

The muon must intersect IceCube's effective area, which for $E_\mu \sim 10$ TeV is roughly 1 km^2 , but is much less for a lower energy muon. We parameterize the effective area, $A_{\text{eff}}(E_\mu)$, for the full IceCube detector following [50, 51]. To model IceCube's energy resolution, we also smear the muon energy spectrum given in Eq. (13) with $\log_{10}(E_{\text{measured}}/E_{\text{real}})$ given by a gaussian distribution centered on zero and with a standard deviation of 0.15 [46]. The total number of muons detected by IceCube is then given by integrating this smeared energy spectrum over all muon energies from E_{th} up to m_χ .

To calculate the muon background, we find $dN_{\nu_\mu, \bar{\nu}_\mu}/dE_\nu$ from atmospheric neutrinos using an average over zenith angle from [52]. We assume a constant pointing resolution of 1° radius down to neutrino energies of 100 GeV for IceCube [53], which should be obtainable given Segue 1's zenith angle of $\sim 106^\circ$ with respect to the South Pole.

By fixing the ratio of signal muons to the square root of the signal plus background, $\langle\sigma v\rangle$ can be determined as a function of m_χ .

While the experimental properties quoted above refer specifically to IceCube, the inclusion of DeepCore [46] in conjunction with IceCube will help in the reconstruction of muon events (ensuring a better pointing accuracy) and in the differentiation of background events.

III. RESULTS

Current and Projected Observations

Below we discuss current and projected experimental flux limits and resulting cross-section bounds.

Fermi — Fermi has reported gamma-ray constraints on 14 nearby dwarf galaxies from 11 months of data in [31]. For Segue 1, Fermi has only reported a flux limit of $4 \times 10^{-10} \text{ cm}^{-2} \text{ s}^{-1}$ for photons above 100 MeV and below 300 GeV using 3 months of data [54, 55]. They assumed a source spectrum of $\frac{dN_\gamma}{dE_\gamma} \sim \frac{1}{E_\gamma}$, which is very close to the FSR spectrum. (Note that the photons from τ decays into π^0 's follow a different spectrum.) Since no signal was seen from Segue 1 in the 9-month data [56, 57], we conservatively take the flux limit from the 3-month data and divide by $\sqrt{3}$ to arrive at an approximate 9-month

FIG. 4: Projected number of muon signal events coming from neutrinos originating from dark matter annihilation directly into muons (left) or into muons through an intermediate particle ϕ (right) in Segue 1, after 10 years of observation with IceCube, and assuming the mean value of $\mathcal{L}_{\text{ann}}^{\text{Segue1}}$ given in Eq. (3). Green and orange regions indicate the best-fit regions to explain the PAMELA and Fermi e^+/e^- signals and are adapted from [20] after rescaling from a local dark matter density of $0.3 \text{ GeV}/\text{cm}^3$ to $0.43 \text{ GeV}/\text{cm}^3$ [47]. Note that these projections do not assume any additional Sommerfeld enhancement in the dwarf galaxy compared to locally. However, if present, such an enhancement could effectively shift up by an order of magnitude or more the PAMELA/Fermi regions in the right plot, increasing the expected number of signal events.

flux limit ($2.3 \times 10^{-10} \text{ cm}^{-2} \text{ s}^{-1}$). (Fermi has not yet presented flux limits on a $1/E_\gamma$ spectrum using more than 3 months of data. The analysis in [23] uses 9 months of data to constrain the “Constrained Minimal Supersymmetric Standard Model”.) This simple scaling expected from statistics is corroborated by Fermi’s results for a $1/E_\gamma^2$ spectrum for which they did present results using 3 and 9 months of data: the flux limits for Segue 1 were $3.1 \times 10^{-9} \text{ cm}^{-2} \text{ s}^{-1}$ [55] and $1.83 \times 10^{-9} \text{ cm}^{-2} \text{ s}^{-1}$ [56, 57], respectively. (It does, however, ignore any improvements that may have been made to the analysis in the meantime, which could further strengthen the limits.) As expected, these limits are worse than the flux limit for a $1/E_\gamma$ signal spectrum, which has more photons at higher energies.

ACTs — Segue 1 has been observed by MAGIC and a flux upper limit of roughly $10^{-12} \text{ cm}^{-2} \text{ s}^{-1}$ above 100 GeV has been reported [58]. This limit should be viewed as an order of magnitude estimate as the exact limit will depend on the shape of the spectrum considered. This limit is for observations of Segue 1 within 0.1 degrees of its center.

IceCube — For IceCube, we show both the number of signal muon events expected and the cross-section bounds assuming $(\text{signal muon events})/\sqrt{\text{signal} + \text{background muon events}} > 2$. We assume an energy threshold of 100 GeV, a pointing resolution of 1° in radius that is constant with energy, and 10 years of observations.

Cross-Section Bounds

From Gamma-rays — In Figure 1, we show the current upper bounds on the dark matter cross-section as a function of mass from Fermi and MAGIC observations of Segue 1. We consider the channels $\chi\chi \rightarrow W^+W^-$, $b\bar{b}$, $t\bar{t}$, and $g\bar{g}$. Figure 2 shows the current upper bounds for the channels $\chi\chi \rightarrow e^+e^-$, $\chi\chi \rightarrow \mu^+\mu^-$, $\chi\chi \rightarrow \tau^+\tau^-$, $\chi\chi \rightarrow \phi\phi \rightarrow e^+e^-e^+e^-$, $\chi\chi \rightarrow \phi\phi \rightarrow \mu^+\mu^-\mu^+\mu^-$, and $\chi\chi \rightarrow \phi\phi$, with $\phi \rightarrow e^+e^-$ 90% of the time, and $\phi \rightarrow \gamma\gamma$ 10% of the time. Here χ denotes the dark matter particle, while ϕ denotes an intermediate particle such as a gauge boson or a scalar. For the case that ϕ goes to $\gamma\gamma$ 10% of the time, ϕ is a light scalar that mixes with the Standard Model Higgs boson. The channels in Figure 2 can give rise to the e^+ and $e^+ + e^-$ excesses observed by PAMELA and Fermi/HESS, as can various combinations of these channels with different branching ratios. In all cases, we consider the mass of ϕ to be $m_\phi \lesssim \mathcal{O}(\text{GeV})$. This kinematically constrains the ϕ to decay to Standard Model particles that include a sizeable lepton fraction and avoids the overproduction of anti-protons. This can also lead to Sommerfeld enhanced annihilation (see below).

In these figures, the solid lines correspond to constraints using the mean $\mathcal{L}_{\text{ann}}$ values *minus* the 2σ errors as given in Table I within $\theta = 0.25$ (for Fermi) and $\theta = 0.1$ (for MAGIC). Thus the solid lines show very conservative 95% confidence level upper limits. The dashed lines use the mean $\mathcal{L}_{\text{ann}}$ values *plus* the 2σ errors showing an optimistic reach. The green and orange regions indicate the best-fit regions to explain the

FIG. 5: Prospective exclusion regions for IceCube 10-year observations of Segue 1. The IceCube constraints assume (signal muon events)/ $\sqrt{\text{signal} + \text{background muon events}} \geq 2$. The muons observed by IceCube are assumed to come from neutrinos produced by dark matter annihilation directly into muons (left) or into muons through an intermediate particle ϕ (right). The solid (dashed) line uses the 2σ lower (upper) limit on $\mathcal{L}_{\text{ann}}$ in Eq. (3). Green and orange regions indicate the best-fit regions to explain the PAMELA and Fermi e^+/e^- signals and are adapted from [20] after rescaling from a local dark matter density of $0.3 \text{ GeV}/\text{cm}^3$ to $0.43 \text{ GeV}/\text{cm}^3$ [47].

PAMELA and Fermi e^+/e^- signals and are adapted from [20]. Note, however, that we scaled down the regions in [20] from a local dark matter density of $0.3 \text{ GeV}/\text{cm}^3$ to $0.43 \text{ GeV}/\text{cm}^3$ [47].

Figures 1 and 2 show that Fermi has an advantage over ACTs for those dark matter channels that produce softer photons. Fermi’s much lower photon energy threshold compared to that of the ACTs ($\sim 100 \text{ MeV}$ versus $\sim 100 \text{ GeV}$) also gives it an advantage in determining cross-section bounds for lower dark matter masses $\mathcal{O}(100 \text{ GeV})$. ACTs have an advantage over Fermi in constraining models which produce harder photon spectra, assuming that the dark matter mass is above the ACT’s threshold of around 100 GeV . This is because ACTs in general have larger collecting areas than Fermi ($\sim 10^4 \text{ m}^2$ versus $\sim 1 \text{ m}^2$) and thus have better statistics at high photon energies.

In Figure 1, the results for the $\chi\chi \rightarrow W^+W^-$ channel show that the Wino LSP model can be probed by gamma-ray observations of Segue 1. This model, which can also explain the PAMELA data, predicts an annihilation cross-section of $\sim 2.5 \times 10^{-24} \text{ cm}^3 \text{ s}^{-1}$ for $m_\chi \simeq 180 \text{ GeV}$ (indicated by the black dot) [40]. While the observations disfavor this model (requiring a value for $\mathcal{L}_{\text{ann}}$ less than its mean for consistency) they are unable to rule it out due to the uncertainty in $\mathcal{L}_{\text{ann}}$. (Note that this model also predicts gamma-ray lines, and limits on such lines disfavor it [59]). A more precise determination by the Fermi collaboration of the flux limit, using the photon spectrum for dark matter annihilation into W^+W^- , may set a stricter limit.

In Figure 2, we see that ACTs give stricter constraints than Fermi on dark matter models favored by the PAMELA and/or Fermi/HESS cosmic-ray electron

and positron data. In many cases, the mean value for $\mathcal{L}_{\text{ann}}$ probes the relevant cross-section and mass region, although taking the conservative value for $\mathcal{L}_{\text{ann}}$ only constrains the $\chi\chi \rightarrow \tau^+\tau^-$ channel. Below we discuss in detail how Sommerfeld enhanced annihilation can be probed with Segue 1, which can lead to stronger constraints in the case of dark matter annihilation to ϕ ’s.

From Neutrinos — In Figure 3 (left), we show the number of signal muon events expected as a function of $\langle\sigma v\rangle$ and m_χ , assuming the mean $\mathcal{L}_{\text{ann}}$ value for Segue 1 in Eq. (3), for the channel $\chi\chi \rightarrow \nu_\mu\bar{\nu}_\mu$, while Figure 4 shows the same for the channels $\chi\chi \rightarrow \mu^+\mu^-$ (left) and $\chi\chi \rightarrow \phi\phi \rightarrow \mu^+\mu^-\mu^+\mu^-$ (right).

Figure 3 gives an indication of how well IceCube can probe the “best-case” scenario of dark matter annihilations directly into neutrinos. The right plot in this figure shows the expected neutrino exclusion limits from IceCube observations of Segue 1 for this channel.

Figure 4 shows that if dark matter with $m_\chi > 1 \text{ TeV}$ explains the PAMELA and/or Fermi excesses, one could expect a few muon signal events from Segue 1 for the first of these channels, but perhaps only one for the annihilation channel through an intermediary ϕ . Note that the PAMELA/Fermi best fit regions assume a local dark matter density of $0.43 \text{ GeV}/\text{cm}^3$ [47] — if the local dark matter density is lower, then a few more neutrinos could be expected. Moreover, if the $\mathcal{L}_{\text{ann}}$ value is larger than the mean, then also a few more could be expected. The number of expected neutrinos could also be larger in the case of Sommerfeld enhanced models, where the low velocity dispersion of the dwarf galaxy may lead to a larger dark matter annihilation cross-section in the dwarf galaxy compared to locally (see below).

Figure 5 shows the expected neutrino exclusion limits from IceCube observations of Segue 1 for the same channels. For both annihilation channels, the ACT prospects are better than those from IceCube for low dark matter masses; for high dark matter masses (above the preferred PAMELA/Fermi regions) both are comparable. However, the observing time for ACTs is of order a few days whereas for IceCube it is years.

We note that neutrinos from dwarf galaxies are less sensitive probes of dark matter annihilation to charged leptons than are observations of neutrinos from the Galactic center region [60]. However, observations of different dwarf galaxies may be stacked, increasing the sensitivity by a factor of a few, and any resulting neutrino signal together with a corroborating gamma-ray signal would be very strong evidence for dark matter annihilation.

Constraining Sommerfeld enhanced models

In order for annihilating dark matter to explain the PAMELA and/or Fermi/HESS e^-/e^+ excesses, the annihilation cross-section must be $\mathcal{O}(100-1000)$ times larger than the thermal WIMP freeze-out cross-section, which we take to be

$$\langle\sigma v_{\text{rel}}\rangle_{\text{f.o.}} \simeq 2.5 \times 10^{-26} \text{ cm}^3 \text{ s}^{-1}. \quad (17)$$

If the WIMP was produced non-thermally in the early Universe (for example, from the decay of a heavier particle), it can naturally have a large annihilation cross-section [40, 61–63]. However, even if the WIMP was in thermal equilibrium in the early Universe, several mechanisms allow the cross-section to be large today while being much smaller at freeze-out [14–16, 64–68]. The Sommerfeld enhancement [14–16, 65–68] increases the cross-section at low dark matter velocities, v , so that the cross-section can be much larger today in the Milky-Way halo, where $v \sim 10^{-3}$, than during freeze-out, where $v \sim 0.3$. Since the dark matter velocity in dwarfs is $v \sim 10^{-4}$, there may be an additional order of magnitude enhancement in the annihilation cross-section in dwarfs (see also [69–71]). This additional enhancement is not guaranteed, however, since the Sommerfeld effect may saturate for very low v . (In this paper, we do not consider any additional enhancement from the even colder substructure within the dwarf galaxy, but see for example [72].)

The Sommerfeld enhancement occurs when the dark matter particle χ couples to a new mediator ϕ , with mass $m_\phi \ll m_\chi$, that produces an attractive potential between the dark matter particles. The ϕ in turn couples to Standard Model matter — in particular, we imagine that ϕ can decay to e^+e^- or $\mu^+\mu^-$, so that dark matter annihilation $\chi\chi \rightarrow \phi\phi \rightarrow e^+e^-e^+e^-$ or $\chi\chi \rightarrow \phi\phi \rightarrow \mu^+\mu^-\mu^+\mu^-$, or a combination, can produce the cosmic-ray excesses (in many models, and depending on m_ϕ , ϕ decays will also produce light hadrons). In this section, we show that gamma-ray observations of Segue 1 disfavor low masses

for ϕ , $m_\phi \sim \mathcal{O}(0.1 \text{ GeV})$, assuming the mean value for $\mathcal{L}_{\text{ann}}$, although the uncertainty in $\mathcal{L}_{\text{ann}}$ does not allow one to conclusively rule out such low masses.

To calculate the Sommerfeld enhancement, we assume that the dark matter couples to a mediator ϕ with coupling strength λ , and we consider two cases. The first case assumes that the dark matter interaction with ϕ is purely *elastic*, while the second case assumes that the interaction is purely *inelastic*. The latter case occurs in the presence of an additional excited dark matter state χ^* so that the interaction with ϕ is only off-diagonal (i.e. χ couples only inelastically to $\chi^*\phi$, and not elastically to $\chi\phi$). We denote the mass splitting between χ and χ^* by δ . The Sommerfeld enhancement in the presence of an excited state has been investigated in detail in [73], where it was found that generically it predicts larger enhancements compared to the elastic case. Excited states occur in many models, including the “inelastic dark-matter” [74] and “exciting dark matter” models [75].

For the elastic case, we model the interaction with an attractive Yukawa potential of the form (following [15])

$$V(r) = -\frac{\alpha_D}{r} e^{-m_\phi r}, \quad (18)$$

where $\alpha_D = \lambda^2/4\pi$. The wave-function of two annihilating dark matter particles in the non-relativistic limit is found by solving the Schrödinger equation,

$$\psi''(r) - m_\chi V(r)\psi(r) + v^2 m_\chi^2 \psi(r) = 0, \quad (19)$$

with the boundary condition $\psi'(\infty) = i v m_\chi \psi(\infty)$ and with $\psi(0)$ arbitrary. The total annihilation cross-section is then given by

$$\begin{aligned} (\sigma v_{\text{rel}}) &= S_0 (\sigma v_{\text{rel}})_0 \\ &\equiv \left| \frac{\psi(\infty)}{\psi(0)} \right|^2 (\sigma v_{\text{rel}})_0, \end{aligned} \quad (20)$$

where $v = v_{\text{rel}}/2$ is the dark matter particle’s velocity in the center-of-mass frame, S_0 denotes the Sommerfeld enhancement in the elastic case, and

$$(\sigma v_{\text{rel}})_0 = \frac{\pi \alpha_D^2}{m_\chi^2} \quad (21)$$

is the cross-section for $\chi\chi \rightarrow \phi\phi$ annihilation. This cross-section is modified if there are additional states into which χ can annihilate, but we will not consider this possibility (however see [76, 77]). In the limit $v \ll 1$ and $m_\phi \ll m_\chi$, Eq. (19) may be solved exactly to give

$$S_0 = \frac{\alpha_D \pi}{v} \left(1 - e^{-\alpha_D \pi/v} \right), \quad (22)$$

which clearly shows the $1/v$ dependence of the cross-section. Away from this limit, the solution to equation (19) must be numerically integrated; it has resonances and saturates when $v \sim m_\phi/m_\chi$. Note that for $\alpha_D \ll v$, Eq. (22) can be expanded to give

$$S_0 \simeq 1 + \frac{1}{2} \frac{\pi \alpha_D}{v} + \frac{1}{12} \left(\frac{\pi \alpha_D}{v} \right)^2. \quad (23)$$

FIG. 6: The Sommerfeld enhanced annihilation cross-section as a function of dark matter mass m_χ for a mediator mass of $m_\phi = 0.1$ GeV and dark matter mass splitting $\delta = 0$ (upper left), $m_\phi = 1$ GeV and $\delta = 0$ (upper right), $m_\phi = 0.25$ GeV and $\delta = 1$ MeV (lower left), and $m_\phi = 1.0$ GeV and $\delta = 1$ MeV (lower right) assuming the dark matter velocity dispersion of the Milky-Way halo (lower purple line) or Segue 1 (upper blue line). Here $\delta = 0$ refers to dark matter without excited states, while $\delta \neq 0$ refers to the splitting between the dark matter ground state and an excited state. The coupling α_D between the dark matter and ϕ is a function of m_χ and has been set to the value that gives the correct thermal relic abundance. Note that $\beta \equiv v/c$. Limits from MAGIC observations of Segue 1 are shown in black solid or dashed lines, where the solid line uses the mean value of $\mathcal{L}_{\text{ann}}$ and the upper (lower) dashed line uses the 2σ lower (upper) bound on $\mathcal{L}_{\text{ann}}$ for Segue 1 (see Eq. (3)). Green and orange regions indicate the best-fit regions to explain the PAMELA and Fermi e^+/e^- signals for $\phi \rightarrow e^+e^-$ (upper plots) and for $\phi \rightarrow \mu^+\mu^-$ (lower plots) and are adapted from [20] after rescaling from a local dark matter density of $0.3 \text{ GeV}/\text{cm}^3$ to $0.43 \text{ GeV}/\text{cm}^3$ [47]. Note that the purple lines intersect, or at least come close to, the PAMELA/Fermi preferred regions. This figure shows that a wide range of values for m_ϕ can be probed and that, in particular, $m_\phi \sim 0.1$ GeV is slightly disfavored by current constraints (upper left plot).

A useful analytical formula [68, 78] that closely matches the numerical solution can be obtained by using the Hulthén potential $V(r) = -\alpha_D m_\phi e^{-r m_\phi} / (1 - e^{-r m_\phi})$, which has similar behavior to the Yukawa potential for $r \rightarrow 0$ and $r \rightarrow \infty$. The solution is given by

$$S_0(v) = \left(\frac{\pi}{\epsilon_v}\right) \frac{\sinh\left(\frac{12\epsilon_v}{\pi\epsilon_\phi}\right)}{\cosh\left(\frac{12\epsilon_v}{\pi\epsilon_\phi}\right) - \cos\left(2\pi\sqrt{\frac{6}{\pi^2\epsilon_\phi} - \frac{36\epsilon_v^2}{\pi^4\epsilon_\phi^2}}\right)}, \quad (24)$$

where

$$\epsilon_v = \frac{v}{\alpha_D c}, \quad \epsilon_\phi = \frac{m_\phi}{\alpha_D m_\chi}. \quad (25)$$

We will use this analytic formula in the calculation of the Sommerfeld enhancement in the elastic case as described below.

In order to calculate the Sommerfeld enhancement in the Milky-Way halo and in Segue 1 today, we proceed as follows (see also [76, 77, 79]). First we use Eqs. (21) and (23) to set the annihilation cross-section in Eq. (20) equal to the cross-section that gives the correct thermal relic

abundance during freeze-out, Eq. (17). This allows us to capture the Sommerfeld effect during freeze-out, where, although much less important than in the Milky-Way and dwarf halo now, it can still enhance the dark matter annihilation cross-section by an $\mathcal{O}(1)$ amount [76, 77, 80–82]. For a given m_χ , this allows us to calculate α_D . The precise value of m_ϕ is not very important, and the use of the simple formula Eq. (23) as opposed to its more complicated variations is sufficient. Moreover, we use $v \sim 0.1$ (as opposed to the canonical value $v \sim 0.3$) for the velocity of the dark matter during freeze-out and have checked that the resulting value of α_D as a function of m_χ agrees to within about 10% with a detailed calculation of the thermal relic abundance in [76]. The resulting value of α_D may now be used to calculate the Sommerfeld enhancement in the Milky-Way and Segue 1 halo. In particular, we take the dark matter distribution to be thermal so that the thermally averaged Sommerfeld enhanced annihilation cross-section is given by [76]

$$\langle \sigma v_{\text{rel}} \rangle \simeq (\sigma v_{\text{rel}})_0 \bar{S}_0, \quad (26)$$

with

$$\bar{S}_0 \equiv \frac{(2/v_0^2)^{3/2}}{2\sqrt{\pi}N} \int_0^{v_{\text{max}}} S_0\left(\frac{v_{\text{rel}}}{2}\right) e^{-\frac{v_{\text{rel}}^2}{2v_0^2}} dv_{\text{rel}}, \quad (27)$$

where $N = \text{erf}(z/\sqrt{2}) - \sqrt{2/\pi} z e^{-z^2/2}$ with $z \equiv v_{\text{esc}}/v_0$, v_{esc} is the dark matter escape velocity, and v_{max} is the maximum relative dark matter velocity in the laboratory frame, which we will simply set equal to v_{esc} . Here we use the analytic formula for S_0 given in Eq. (24), and take for the Milky-Way [83]

$$v_0 \simeq 210 \text{ km/s}, \quad v_{\text{esc}} \simeq v_{\text{max}} \simeq 525 \text{ km/s} \quad (28)$$

(these values are close to other values in the literature, e.g. [84, 85], and allow us to compare our results to those in [76]). For Segue 1, the average one-dimensional dark matter velocity dispersion within a 0.25° radius from the center is 4.5 ± 1.8 km/s. This was obtained using Eq. (4). The relevant parameters we use for Segue 1 are

$$v_0 \simeq \sqrt{2} \times 4.5 \text{ km/s} \simeq 6.4 \text{ km/s}, \quad v_{\text{esc}} \sim v_{\text{max}} \sim 10 \text{ km/s}. \quad (29)$$

We note that small variations in the value of v_{esc} and v_{max} for Segue 1 do not qualitatively impact the results.

In Figure 6 (upper two figures), we show the resulting Sommerfeld enhanced annihilation cross-section as a function of m_χ for $m_\phi = 0.1$ GeV (upper left) and $m_\phi = 1$ GeV (upper right) for dark matter annihilating in the Milky-Way halo (purple line) and in Segue 1 (blue line). We superimpose these on the PAMELA/Fermi preferred region adapted from [20], for the case that ϕ decays exclusively to e^+e^- , after rescaling their values from a local dark matter density of 0.3 GeV/cm^3 to 0.43 GeV/cm^3 [47][99]. Note that the purple line does intersect the PAMELA/Fermi preferred region, as it must if it is to explain this data. The gamma-ray constraints

from MAGIC observations of Segue 1 are shown in black lines, with the solid line using the mean value of $\mathcal{L}_{\text{ann}}$, while the upper dashed shows the conservative limit with $\mathcal{L}_{\text{ann}} - 2\sigma$, and the lower dashed line shows the optimistic limit with $\mathcal{L}_{\text{ann}} + 2\sigma$. We see that the additional Sommerfeld enhancement expected in Segue 1 (indicated by the blue line) allows us to constrain this model. In particular, low values of m_ϕ are disfavored assuming the mean value for $\mathcal{L}_{\text{ann}}$, although they cannot be ruled out due to the uncertainty in $\mathcal{L}_{\text{ann}}$. Since the Sommerfeld enhancement saturates when $v \lesssim m_\phi/m_\chi$, larger m_ϕ are less constrained. However, even for larger $m_\phi \sim \mathcal{O}(1 \text{ GeV})$ a sizeable fraction of the parameter space lies near a resonance region, and is constrained.

For the elastic case and for ϕ decaying exclusively to $\mu^+\mu^-$, the α_D required by thermal freeze-out is too small to give a large enough Sommerfeld enhanced annihilation cross-section to explain the PAMELA/Fermi regions [76]. Inelastic interactions increase the cross-section and alleviate the discrepancy [73, 77]. In Figure 6 (lower two plots), we show the resulting Sommerfeld enhanced annihilation cross-section as a function of m_χ for $\delta = 1$ MeV for $m_\phi = 0.25$ GeV (lower left) and $m_\phi = 1$ GeV (lower right) for dark matter annihilating in the Milky-Way halo (purple line) and in Segue 1 (blue line). We review the details of the Sommerfeld enhancement in the presence of excited states in Appendix A (note that we ignore any complications in the freeze-out calculation of having additional excited states). For the case in which ϕ decays exclusively to $\mu^+\mu^-$, we superimpose these on the PAMELA/Fermi preferred region adapted from [20], again rescaling their results to a local dark matter density of 0.43 GeV/cm^3 (note, however, that the Sommerfeld cross-sections are independent of the ϕ decay modes). The gamma-ray constraints from MAGIC observations of Segue 1 are again shown in black lines, and we find that for both small and larger values of m_ϕ , they constrain part of the relevant parameter space.

The purple lines in the two lower plots of Figure 6 lie just below the Fermi region. This small discrepancy can be alleviated in many ways. For example, the local dark matter density may be larger than the value assumed here, 0.43 GeV/cm^3 . Moreover, taking into account substructure which enhances the positron and electron flux can lower the required cross-section by another factor of two [86, 87]. Uncertainties in the astrophysical backgrounds and in the cosmic-ray propagation can further lower the required cross-section and remove the discrepancy (see e.g. [88, 89]). In addition, the PAMELA/Fermi regions assume that ϕ annihilates exclusively to $\mu^+\mu^-$. In many models, however, ϕ will decay also at least partly to e^+e^- , which lowers the required cross-section further, while still providing an excellent fit to the data. This is the case, for example, in which dark matter is charged under a new GeV-scale Abelian force that kinetically mixes with hypercharge, see e.g. [15–18, 75, 77].

The next generation of ACTs such as AGIS [100] and CTA [90] will improve the current prospects by

roughly an order of magnitude, and will significantly constrain Sommerfeld enhanced models that explain the Fermi/PAMELA signals. The current and future prospects from gamma-ray observations of dwarf galaxies are complementary to those coming from current constraints of WMAP observations of the Cosmic Microwave Background and prospective constraints from Planck [91–94].

IV. CONCLUSIONS

The Milky Way satellite Segue 1 is the least luminous and most dark-matter dominated galaxy known. Using a new sample of member stars, we have derived a new value for the line-of-sight integral of the dark matter halo density-squared, $\mathcal{L}_{\text{ann}}$. Its mean value is similar to the same quantity for Draco and larger than that for all other known dwarfs. With this new value, we have derived robust upper limits on dark matter annihilation cross-sections from gamma-ray flux upper limits from Fermi and the Imaging Atmospheric Cherenkov Telescope (ACT) MAGIC, and have shown that these constraints may in fact be much stronger given the significant uncertainty remaining in the Segue 1 dark matter distribution. For a mean value of the Segue 1 density-squared integral, the constraints we present are more stringent than those obtained from any other Milky Way dwarf spheroidals to date (see e.g. [31, 95, 96]).

We showed that Fermi and ACTs are complementary in the dark matter models they can probe, with Fermi having an advantage over ACTs for dark matter channels that produce softer photons as well as for lower dark matter masses $\lesssim \mathcal{O}(100 \text{ GeV})$. ACTs have an advantage over Fermi in constraining cross-sections for larger dark matter masses $\gtrsim \mathcal{O}(100 \text{ GeV})$.

The flux limits do not rule out a dark matter explanation for the PAMELA/Fermi/HESS e^+/e^- signals, but probe the relevant regions. With its low dark matter velocity dispersion, Segue 1 also serves as a useful laboratory for constraining Sommerfeld enhanced models that have been invoked to explain these signals. We find that current constraints from MAGIC slightly disfavor light mediators of mass $\mathcal{O}(0.1 \text{ GeV})$ if we take the mean value for $\mathcal{L}_{\text{ann}}$. However, due to the uncertainty in the dark matter density in Segue 1, such light force carriers cannot at this stage be ruled out.

In addition, we show that under favorable circumstances neutrino observatories such as IceCube also have the potential to detect a dark matter signal from Segue 1, providing an important cross-check, for some channels, if a signal is detected in the gamma-rays.

Since Segue 1 lies in the Northern Hemisphere, it is an excellent target for the VERITAS and MAGIC, and for IceCube. Observations by MAGIC (and future observations by VERITAS) are able to set interesting and robust constraints on dark matter annihilation, with rather modest observing times directed at Segue 1. Moreover, the ACT constraints presented here may be considerably

improved if these instruments are able to lower their energy thresholds, observe over longer times, and perform an analysis specifically aimed at models that explain the e^+/e^- signals.

Though our analysis has focused on the galaxy Segue 1, prospects are promising for strengthening the limits we have presented. Given selection effects and biases in current surveys for MW satellites, it is probable that the population of nearby, dark-matter dominated satellites will increase in the near future [97]. Any signal from one dwarf can thus be corroborated by looking at others. Moreover, the significance of a signal or of a limit can be improved by stacking together the observations of several dwarf galaxies. In addition, the next generation of ACTs such as AGIS and CTA will improve the current prospects by roughly an order of magnitude. These improvements will allow a definitive probe of many dark matter annihilation models.

Appendix A: Sommerfeld enhancement in the presence of an excited dark matter state

In this brief Appendix, we summarize the formulas needed to calculate the Sommerfeld enhancement in the presence of an excited state [73]. The Sommerfeld effect can be calculated numerically, however [73] presented a computationally less intensive semi-analytical formula, which we review here. We refer the reader to [73] for all the details, and mostly use the same notation.

We take the mass-splitting between the dark matter ground state and excited state to be δ , and define

$$\epsilon_v = \frac{v}{\alpha_D c}, \quad \epsilon_\phi = \frac{m_\phi}{\alpha_D m_\chi}, \quad \epsilon_\delta = \sqrt{\frac{2\delta}{m_\chi}} \frac{1}{\alpha_D}, \quad (\text{A1})$$

For $\epsilon_v, \epsilon_\phi, \epsilon_\delta \ll 1$ and for $\delta \lesssim \max(\alpha_D m_\phi, m_\chi (v/c)^2)$, the Sommerfeld enhanced annihilation of the ground-state is given by

$$S(v) = \frac{2\pi}{\epsilon_v} \sinh\left(\frac{\pi\epsilon_v}{\mu}\right) \times \begin{cases} \frac{1}{\cosh\left(\frac{\pi\epsilon_v}{\mu}\right) - \cos\left(\frac{\pi}{\mu}\sqrt{\epsilon_\delta^2 - \epsilon_v^2} + 2\theta_-\right)} & \epsilon_v < \epsilon_\delta, \\ \frac{\cosh\left(\frac{\pi}{2\mu}(\epsilon_v + \sqrt{-\epsilon_\delta^2 + \epsilon_v^2})\right) \operatorname{sech}\left(\frac{\pi}{2\mu}(\epsilon_v - \sqrt{-\epsilon_\delta^2 + \epsilon_v^2})\right)}{\cosh\left(\frac{\pi}{\mu}(\epsilon_v + \sqrt{-\epsilon_\delta^2 + \epsilon_v^2})\right) - \cos(2\theta_-)} & \epsilon_v > \epsilon_\delta. \end{cases} \quad (\text{A2})$$

Here

$$\mu = \epsilon_\phi \left(\frac{1}{2} + \frac{1}{2} \sqrt{1 + \frac{4}{\epsilon_\phi r_M}} \right) \quad (\text{A3})$$

$$\theta_- = \int_{z_M}^{\infty} \frac{dz}{2\mu z} \left(\sqrt{\left| \epsilon_v^2 - \frac{1}{2}\epsilon_\delta^2 + \sqrt{\left(\frac{1}{2}\epsilon_\delta^2\right)^2 + 16\mu^4 z} \right|} - 2\mu z^{\frac{1}{4}} \right) - 4z_M^{\frac{1}{4}} - \int_0^{r_M} dr \sqrt{|\lambda_-|} \quad (\text{A4})$$

where r_M and z_M are defined by

$$\frac{e^{-\epsilon_\phi r_M}}{r_M} = \max\left(\frac{\epsilon_\delta^2}{2}, \epsilon_\phi^2\right) \quad (\text{A5})$$

$$z_M = \max\left(\frac{\epsilon_\delta^4}{64\mu^4}, \frac{\epsilon_\phi^4}{16\mu^4}\right), \quad (\text{A6})$$

and λ_- is given by

$$\lambda_-(r) = -\epsilon_v^2 + \frac{\epsilon_\delta^2}{2} - \sqrt{\left(\frac{1}{2}\epsilon_\delta^2\right)^2 + \frac{e^{-2\epsilon_\phi r}}{r^2}}. \quad (\text{A7})$$

In the lower two figures in Figure 6, we show the Sommerfeld enhanced annihilation cross-section for $\delta = 1$ MeV. Note that here we did not thermally average the cross-section, which is computationally very intensive, but rather took 150 km/s for the Milky-Way dark matter

velocity and 4.5 km/s for that of Segue 1. For the region of interest around $m_\chi \sim \mathcal{O}(1 \text{ TeV})$, we checked that the resulting cross-section is $\sim 20\%$ *lower* than the thermally averaged cross-section.

- [98] We note that including the two RR Lyrae variable stars and two probable binaries has minimal effect on our results.
- [99] We note that the cosmic-ray spectrum obtained from ϕ 's decaying exclusively to e^+e^- gives a slightly worse fit to the PAMELA/Fermi spectra than if one, for example, assumes additional hidden sector showering, or ϕ decays to electrons and muons, or only to muons [20]. We refer the reader to [77] for a detailed discussion and benchmark points consistent with the PAMELA/Fermi spectra and preferred regions in the cross-section and mass plane.
